Video capsule endoscopy in the diagnosis of Peutz-Jeghers syndrome

Videocápsula endoscópica en el diagnóstico del síndrome de Peutz-Jeghers

Video capsule endoscopy (VCE) is a diagnostic technique utilized in the majority of polyposis syndromes to detect lesions in the small bowel.1

We present herein the case of a 66-year-old man who sought medical attention for suboccclusive symptoms presenting over the last few months, that alternated with periods of no symptoms. VCE was performed as soon as the patient presented with a low probability of obstruction, observing numerous polyps of different size and stage that extended from the antrum to the colon (Fig. 1A–C). The study was completed through colonoscopy, with the extirpation of several of the polyps. The histologic analysis stated hamartomatous polyps. The patient is currently in follow-up with endoscopic examinations and periodic polypectomies,2 including resection of jejunal polyps with a double balloon enteroscope.

According to the literature, one of the indications for VCE is the diagnosis of small bowel polyposis syndromes, as in the present case. That diagnostic method has shown greater sensitivity than other imaging studies and a similar detection rate to that of double balloon enteroscopy, as well as a low complication rate. However, VCE has a series of disadvantages with respect to imaging studies, such as interobserver variability in its interpretation and its limitation for determining lesion size. In the present case, we wish to emphasize the role of VCE as a simple, efficacious, radiation-free diagnostic method, with a low complication rate, in the study of patients with gastrointestinal polyposis syndromes. Evaluation is later completed with more specific techniques, enabling the most accurate diagnosis possible.

Stricturing ulcerative colitis: a case of rapid disease progression

Colitis ulcerosa con estenosis: un caso de progresión rápida de la enfermedad

Ulcerative colitis (UC) is considered an idiopathic disease of the large bowel that consists of chronic mucosal inflammation due to a complex interaction between genetic predisposition and environmental factors. Worldwide incidence is reported to have plateaued in North America (19.2 per 100,000 person-years) and Europe (24.3 per 100,000 person-years), whereas low incidence regions, specifically in developing countries, appear to have experienced an increase in inflammatory bowel disease (IBD) that is most likely due to industrialization.\textsuperscript{1} Epidemiologic data on UC are scarce in those countries, as they are in Mexico. In a recently published nationwide cohort study, encompassing more than 15 years (2000-2017), incidence was reported at 0.16 per 100,000 person-years and prevalence at 1.45 per 100,000 person-years for UC in Mexico, revealing a 5.3-fold increase.\textsuperscript{2} The extent and clinical course of the disease can vary, ranging from rectal involvement to pancolitis in a continuous manner, and the disease is characterized by a relapsing and remitting course. The phenotype at diagnosis in patients with UC is generally split equally between proctitis, left-sided disease, and pancolitis. Both IBD subtypes, namely UC and Crohn’s disease (CD), are chronic diseases consisting of chronic inflammation with subsequent constant tissue repair. CD presents with transmural disease with activation of mesenchymal cells and a subsequent stricturing disease course, whereas fibrosis and scar formation in long-standing UC is usually limited to the mucosa, including pseudopolyps and bridging fibrosis.\textsuperscript{4} An increased risk of colorectal cancer has been recognized for UC, in particular, with a cumulative incidence of 2% in 10 years, 8% in 20 years, and 18% in 30 years.\textsuperscript{5} Those data highlight why neoplasia should be the primary suspicion when a colonic stricture is diagnosed. Nevertheless, in their original articles dating back to 1964, Edwards and Truelove reported benign stric-
